Abstract

We show that the notion of mutual statistics arises naturally from the representation theory of the braid group over the multi-sheeted surface. A Hamiltonian which describes particles moving on the double-sheeted surface is proposed as a model for the bilayered fractional quantum Hall effect (FQHE) discovered recently. We explicitly show that the quasi-holes of the bilayered Hall fluid display fractional mutual statistics. A model for 3-dimensional FQHE using the multi-layered sample is suggested.

1 Introduction

Anyons, or particles with quantum statistics interpolating between bosons and fermions [1], are associated with interesting 2-dimensional condensed matter physics. By now, it is quite established that the quasi-particle and quasi-hole excitations of the fractional quantum Hall effect (FQHE) obey anyonic statistics. The experiments probing the behaviour of the longitudinal resistance [2], together with those studying the transmission probability and reflection probability between two electron liquids [3] provide clear evidence that the quasi-excitation is fractionally charged, a fact best described by a theory which treats the quasi-excitation as anyon [4]. The studies of anyons have also led to a novel model of superconductivity [5, 6], which may or may not have any relevance to the physics of superconducting materials with high critical temperature. It is also noteworthy that the concept of anyon or braid group statistics has been generalized to the nonabelian case [7, 8], and particles on Riemann surfaces of higher genus [9].

Though the possibility of such exotic statistics is peculiar to 2-dimensional many-body quantum system, there is still one aspect of quantum statistics that has not been well excogitated. One is used to the notion that quantum statistics is about particles being indistinguishable. However, in two dimensional systems, even particles which are distinguishable can be assigned with a “statistics” when they exchange their positions.

Recently, with the experimental discoveries of FQHE at filling factor $\nu = \frac{1}{2}$, Wilczek went further and introduced the term “mutual statistics” [10, 11]. It is a novel idea prompted by the observation of this new fractional quantum Hall state in *double*-layered two-dimensional electronic systems.

The experimental realization of a $\nu = \frac{1}{2}$ FQHE has been much sought after and its discovery is exciting indeed. Two research groups, Suen *et al.* [12] and Eisenstein *et al.* [13] have independently found the $\nu = \frac{1}{2}$ magneto-transport spectrum, albeit with different sample geometries. While on the scale of the magnetic length ℓ , the former group used a wide GaAs/AlGaAs single quantum well to realize the bilayered electronic system, the latter’s samples contained two narrow quantum wells separated by an undoped pure AlAs barrier layer. At this stage, it is not clear whether these two states with the same filling factor are in the same universality class [14]. Certainly, different geometries give rise to different profiles of the distribution functions of the system along the direction normal to the surface of the sample. Nevertheless, for the discussion of mutual statistics, we shall for the time being assume that the electronic system is ideally bilayered.

The crucial thing about the bilayered system is that one can have two kinds of electrons, by introducing an index to indicate which of the two layers the electrons reside. Furthermore, the layer index can be treated as a kind of quantum number, called “pseudo-spin”, in close analogy to the spin of the electrons[‡]. Thus, the bilayered electronic system

[‡]It is justified to ignore the spin degree of freedom as all the electrons are polarized by the strong

possesses an additional degree of freedom which, as discussed by Yoshioka, MacDonald and Girvin (YMG) [15], allows Laughlin wavefunction to abide in Pauli principle yet describes a FQHE state with *even* denominator filling factor.

Suppose we label the coordinates of those electrons in the first layer with $w_a^{[1]}$ and those in the second layer $w_a^{[2]}$. The ansatz $\psi_{m_1, m_2, n}$ proposed by YMG is an almost trivial generalization of the Laughlin wavefunction:

$$\psi_{m_1, m_2, n}(w_a^{[1]}, w_a^{[2]}) = \prod_{a < b} (w_a^{[1]} - w_b^{[1]})^{m_1} \prod_{a < b} (w_a^{[2]} - w_b^{[2]})^{m_2} \prod_{a, b} (w_a^{[1]} - w_b^{[2]})^n \quad (1)$$

$$\times \exp -\frac{1}{4\ell^2} \left(\sum_a^{N^{[1]}} |w_a^{[1]}|^2 + \sum_a^{N^{[2]}} |w_a^{[2]}|^2 \right). \quad (2)$$

The integers m_1 and m_2 are odd, as entailed by the fact that the electrons in the same layer are indistinguishable. The non-trivial aspect of $\psi_{m_1, m_2, n}$ as a generalization of Laughlin wavefunction lies in the factor $\prod_{a, b} (w_a^{[1]} - w_b^{[2]})^n$ which describes some sort of inter-layer correlation. As their numerical studies indicate, the overlap between the ground state wavefunction of a few electrons interacting via Coulomb potential and $\psi_{m_1, m_2, n}$ is dependent on $\delta = \frac{d}{\ell}$, where d denotes the distance between the layers.

In this article, we shall discuss the topological order of the bilayered FQHE, using the braid group approach we did for single-layered FQHE states [16, 17]. We are interested to find out if the inter-layer correlation characterized by $\prod (w_a^{[1]} - w_b^{[2]})^n$ can be understood within the more fundamental formulation of anyon physics, namely, the theory of the quantum statistics in two spatial dimensions as the representation theory of braid group [18]. The key idea involves generalizing the path integral representation of Artin's braid group to an analogue associated with many-sheeted surfaces. As we shall see, the idea of particles moving freely in the double-sheeted surface gives rise to the notion of mutual statistics.

The paper is presented as follows. In the next section, we review the path integral representation of the braid group [8] and its application [16] to the FQHE of Laughlin type. Using the same method, we proceed to construct a similar representation for the braid group of the double-sheeted plane in section 3. The motivation is to capture the physics of bilayered Hall media within the framework of braid group statistics. In section 4, we show that $\psi_{m_1, m_2, n}$ is an exact solution of the ground state equations. Explicitly, we also illustrate how mutual statistics arises in the braid group approach. In section 5, we discuss various aspects of the multi-layered FQHE. Our method allows us to calculate the filling factors of samples which have arbitrary number of layers. We also touch on the notion of 3-dimensional FQHE. Section 6 summarizes the main results of this paper.

magnetic field.

2 Puncture phase and the braid group

The significance of the braid group for quantum statistics of particles living in two spatial dimensions is clearly discussed by Y. S. Wu [18] who constructed a one-dimensional (abelian) representation in the path integral formalism. The braid group B_N of N threads are generated by generators σ_i , $i = 1, \dots, N-1$ which are defined as the i -th thread crosses *over* the $i+1$ -th thread (Fig. 1).

Fig. 1: The definition of σ_i .

They satisfy the following algebraic relations:

$$\sigma_i \sigma_j = \sigma_j \sigma_i, \quad |i - j| \geq 2, \quad (3)$$

$$\sigma_i \sigma_{i+1} \sigma_i = \sigma_{i+1} \sigma_i \sigma_{i+1}, \quad i = 1, \dots, n-2. \quad (4)$$

The basic idea of the path integral representation [18] is to see the threads as non-relativistic world lines of point particles. Equally important is the observation that the underlying topology of the 2-dimensional plane is non-simply connected when each particle sees others as punctures [8].

2.1 Non-abelian representation of the braid group

Because the configuration space has become multiply connected, the paths are homotopically classified and those of different classes cannot be smoothly deformed from one to the other. When one considers the Feynman kernel for a particle moving from point $z_{a(0)}$ at time t_0 to point $z_{a(1)}$ at time t_1 , one has to organize the paths according to their homotopical classes. Now, the homotopy class of a path in the $N-1$ -punctured configuration space M_{N-1} is determined by the winding numbers with respect to the punctures.

It must be emphasized that the notion of winding around a marked point (puncture) is valid only if the space is 2-dimensional. We formulate the homotopic constraint by introducing the notion of *charged* winding “number”:

$$w = \frac{1}{2\pi i} \int_C \frac{dz_a}{z_a - z_b} T_a \otimes T_b. \quad (5)$$

Here, T_a and T_b are the representations carried by the particles. We see the threads as more than merely worldlines. When the particles carry non-abelian charges, they become Wilson lines. The corresponding charged winding angle θ can now be defined as:

$$\theta = \text{sign}(C) |\theta_{a(1)} - \theta_{a(0)}| + 2\pi w. \quad (6)$$

We choose the convention that a path going counterclockwise about the puncture z_b has positive sign, namely $\text{sign}(C) = 1$, and denote $\vartheta = \text{sign}(C) |\theta_{a(1)} - \theta_{a(0)}|$. With this convention, for the homotopically equivalent paths corresponding to σ_i , which cross over from the left, the change in the azimuthal angle ϑ is non-negative. Compared to Wu’s [18] original construction, Our ϑ is fixed by the initial and final positions of the particle and does not play a significant role here. The constrained Feynman kernel of homotopy class l for particle a with mass m can be expressed formally as:

$$K_l(z_{a(1)}, t_1, z_{a(0)}, t_0) = \int \mathcal{D}_l z_a(t) \mathcal{D}_l \bar{z}_a(t) \exp i \int_{t_0}^{t_1} \frac{1}{2} m |\dot{z}_a(t)|^2 dt \delta^2(2\pi l T_a \otimes T_b - \theta). \quad (7)$$

With the path ordering determined by that in the definition of charged winding angle (6), the matrix-valued Dirac delta function can be represented by the following path-ordered Fourier transform:

$$\delta^2(2\pi l T_a \otimes T_b - \theta) = \iint \frac{dk}{2\pi} \frac{d\bar{k}}{2\pi} e^{-i(k\vartheta + \bar{k}\vartheta)} \text{P exp } i [2\pi k(l T_a \otimes T_b - w) + a.c.]. \quad (8)$$

We use *a.c.* to denote the anti-chiral copy of the preceding terms within the delimiters.

Substituting (8) into the Feynman kernel (7), we obtain the Fourier transform:

$$K_l(z_{a(1)}, t_1, z_{a(0)}, t_0) = \iint \frac{dk}{2\pi} \frac{d\bar{k}}{2\pi} e^{-i(k\vartheta + \bar{k}\vartheta)} \widetilde{K}_l(z_{a(1)}, t_1, z_{a(0)}, t_0; k, \bar{k}), \quad (9)$$

where

$$\begin{aligned} \widetilde{K}_l(z_{a(1)}, t_1, z_{a(0)}, t_0; k, \bar{k}) &= \int \mathcal{D}_l z_a(t) \mathcal{D}_l \bar{z}_a(t) \text{P exp } i \int_{t_0}^{t_1} \frac{1}{2} m |\dot{z}_a(t)|^2 dt \\ &\quad \times \exp i \int_{t_0}^{t_1} \left(k \left(\frac{i \dot{z}_a}{z_a - z_b} + 2\pi l \right) T_a \otimes T_b + a.c. \right) dt. \end{aligned} \quad (10)$$

Expressions (7) and (10) can be easily generalized to N particles at $z_1, z_2, \dots, z_N$, with $\text{Re } z_1 < \text{Re } z_2 < \dots < \text{Re } z_N$. Let particle i make a trip from $z_{i(0)} = z_i(t_0)$ to $z_{i(1)} = z_i(t_1)$, $\text{Re } z_{i(1)} > \text{Re } z_{i+1}$. Denoting the difference in the initial angle and the final angle of the paths of particle i with respect to particle j as ϑ_{ij} , $\vartheta_{ij} = \text{sign}(C_i) |\theta_{ij(1)} - \theta_{ij(0)}|$, the constrained Feynman kernel of homotopy class $(l_1, \dots, l_{i-1}, l_{i+1}, \dots, l_n)$ for particle i carrying representation T_i is

$$K_{l_i}(z_{i(1)}, t_1, z_{i(0)}, t_0) = \iint \frac{dk}{2\pi} \frac{d\bar{k}}{2\pi} \exp \left(-i \sum_{j=1, j \neq i}^n (k\vartheta_{ij} + \bar{k}\vartheta_{ij}) \right) \widetilde{K}_{l_i}(z_{i(1)}, t_1, z_{i(0)}, t_0; k, \bar{k}), \quad (11)$$

where

$$\begin{aligned} \widetilde{K}_{l_i}(z_{i(1)}, t_1, z_{i(0)}, t_0; k, \bar{k}) &= \int \mathcal{D}_{l_i} z_i(t) \mathcal{D}_{l_i} \bar{z}_i(t) \text{P exp } i \int_{t_0}^{t_1} \frac{1}{2} m_i |\dot{z}_i(t)|^2 dt \\ &\times \exp i \int_{t_0}^{t_1} \left(k \sum_{j=1, j \neq i}^n \left(\frac{i \dot{z}_i}{z_i - z_j} + 2\pi l_j \right) T_i \otimes T_j + a.c. \right) dt. \end{aligned} \quad (12)$$

Given these initial and final conditions, σ_i can be represented by the positively oriented Feynman kernel of class $(0, \dots, \hat{0}_i, \dots, 0)$, the i -th 0 is omitted as we do not consider self-linking. Writing,

$$A_{z_i} = ik \sum_{j=1, j \neq i}^N \frac{T_i \otimes T_j}{z_i - z_j}, \quad (13)$$

$$A_{\bar{z}_i} = i\bar{k} \sum_{j=1, j \neq i}^N \frac{\bar{T}_i \otimes \bar{T}_j}{\bar{z}_i - \bar{z}_j}, \quad (14)$$

the proposed representation $D(\sigma_i)$ is $K_i(t_1, t_0)$ given below;

$$\begin{aligned} \int \mathcal{D}_+ z_i \mathcal{D}_+ \bar{z}_i \iint \frac{dk}{2\pi} \frac{d\bar{k}}{2\pi} \text{P exp } i \int_{C_i} \frac{1}{2} m_i |dz_i|^2 + A_{z_i} dz_i + A_{\bar{z}_i} d\bar{z}_i \\ \times \exp \left(-i \sum_{j=1, j \neq i}^N (k\vartheta_{ij} + \bar{k}\vartheta_{ij}) \right), \end{aligned} \quad (15)$$

followed by an exchange operation Π_{i+1} ,

$$D(\sigma_i) = \Pi_{i+1} K_i(t_1, t_0). \quad (16)$$

Π_{i+1} is to make every world line stick to the same representation space it has started with. The multiplication rule for the braid group generators is realised as the usual

multiplication of kernels. One can prove that $D(\sigma_i)$ satisfy the defining relations (3, 4) [8].

Now, the effective Lagrangian of particle i can be readily read from (15).

$$L = \frac{1}{2}m_i|\dot{z}_i|^2 + A_{z_i}\dot{z}_i + A_{\bar{z}_i}\dot{\bar{z}}_i. \quad (17)$$

The Schrödinger equation associated to the Feynman kernel of particle i is

$$i\frac{\partial}{\partial t}\psi = -\frac{1}{m_i}[(\partial_{z_i} - iA_{z_i})(\partial_{\bar{z}_i} - iA_{\bar{z}_i}) + (\partial_{\bar{z}_i} - iA_{\bar{z}_i})(\partial_{z_i} - iA_{z_i})]\psi. \quad (18)$$

In the limit $m_i \rightarrow 0$, a class of solutions of (18) consists of those wavefunctions ψ satisfying

$$(\partial_{z_i} - iA_{z_i})\psi = \left(\frac{\partial}{\partial z_i} + k \sum_{j=1, j \neq i}^N \frac{T_i \otimes T_j}{z_i - z_j}\right)\psi = 0, \quad (19)$$

$$(\partial_{\bar{z}_i} - iA_{\bar{z}_i})\psi = \left(\frac{\partial}{\partial \bar{z}_i} + \bar{k} \sum_{j=1, j \neq i}^N \frac{\bar{T}_i \otimes \bar{T}_j}{\bar{z}_i - \bar{z}_j}\right)\psi = 0. \quad (20)$$

These are precisely the Knizhnik-Zamolodchikov equations if we set $k = \bar{k} = -2/(l + c_V)$, where l is the level of the WZW model and c_V is the quadratic Casimir of the adjoint representation of the group G [19]. It is interesting to note that the wavefunctions, though non-normalizable, are the parallel transport sections of a complex vector bundle over the base manifold M_{N-1} .

In the context of particle statistics, (18) can be interpreted as the Schrödinger equation for non-Abelian anyons. When $T_i = \bar{T}_i = 1$, $i = 1, \dots, N$, it is the (abelian) 1-dimensional irreducible representation constructed by Wu [18]. Therefore our construction is a non-Abelian generalization of the general theory of quantum statistics in two dimensions.

2.2 Laughlin ground state

The starting point of a plausible theory of FQHE is Laughlin's ansatz [4]:

$$|m\rangle = \prod_{j < k} (z_j - z_k)^m \exp\left(-\frac{1}{4\ell^2} \sum_i |z_i|^2\right), \quad (21)$$

where $\ell = \sqrt{\frac{\hbar c}{eB}}$ is the magnetic length, $\hbar$, c being the usual universal constants, e is the charge of the electron and B is the strength of the magnetic field. It is postulated that

$|m\rangle$ is the ground state of the electrons exhibiting FQHE with fractional filling factor $\frac{1}{m}$. The reason why m is odd is because $|m\rangle$ describes a system of electrons which have fermionic statistics.

Let us consider the N -body Hamiltonian:

$$\begin{aligned} H &= \frac{1}{m^*} \sum_{j=1}^N [(-i\hbar\partial_{z_j} + \frac{e}{c}B_{z_j} + A_{z_j})(-i\hbar\partial_{\bar{z}_j} + \frac{e}{c}B_{\bar{z}_j} + A_{\bar{z}_j}) \\ &\quad + (-i\hbar\partial_{\bar{z}_j} + \frac{e}{c}B_{\bar{z}_j} + A_{\bar{z}_j})(-i\hbar\partial_{z_j} + \frac{e}{c}B_{z_j} + A_{z_j})] \\ &= \frac{\hbar^2}{m^*} \sum_{j=1}^N (D_{z_j}D_{\bar{z}_j} + D_{\bar{z}_j}D_{z_j}) , \end{aligned} \quad (22)$$

where

$$D_{z_j} \equiv \partial_{z_j} + i\frac{e}{\hbar c}B_{z_j} + \frac{i}{\hbar}A_{z_j} , \quad (23)$$

$$D_{\bar{z}_j} \equiv -\partial_{\bar{z}_j} - i\frac{e}{\hbar c}B_{\bar{z}_j} - \frac{i}{\hbar}A_{\bar{z}_j} , \quad (24)$$

$$\begin{aligned} A_{z_j} &= im\hbar \sum_{k=1, k \neq j}^N \frac{T_j \otimes T_k}{z_j - z_k} , \\ A_{\bar{z}_j} &= i\bar{m}\hbar \sum_{k=1, k \neq j}^N \frac{\bar{T}_j \otimes \bar{T}_k}{\bar{z}_j - \bar{z}_k} , \end{aligned} \quad (25)$$

m^* is the effective mass of the electron, and $B_{z_j}, B_{\bar{z}_j}$ the components of the gauge field of the external magnetic field. The gauge field components $A_{z_j}, A_{\bar{z}_j}$ reflect the topological properties of the configuration space. Our construction which hinges on formulating the winding number as the homotopy label for the paths therefore is valid if the width of the quantum well is smaller than, or of the order of 2ℓ . A non-trivial consequence is that one should expect the single-layered FQHE to disappear when the width becomes unduly large.

Since all the particles are indistinguishable, they carry the same representation. Thus, for any two particles k, j , we have $T_j = T_k$ and $T_j = \bar{T}_j$, $j = 1, \dots, N$. One may use hermitian matrices to represent T_j^α , $\alpha = 1, \dots, \dim G$. In the symmetric gauge,

$$\begin{aligned} B_{z_j} &= -i\frac{B}{4}\bar{z}_j , \\ B_{\bar{z}_j} &= i\frac{B}{4}z_j , \\ m &= -\bar{m} , \end{aligned} \quad (26)$$

one calculates the commutator of D_{z_i} and $D_{\bar{z}_j}$:

$$[D_{z_j}, D_{\bar{z}_j}] = \frac{eB}{2\hbar c} + 2\pi m \sum_{k=1, k \neq j}^N \delta^{(2)}(z_j - z_k) T_j \otimes T_k. \quad (27)$$

The term $\frac{eB}{2\hbar c}$ is related to the zero-point energy of a simple harmonic oscillator, whereas the Dirac delta functions arise from the 2-dimensional Green function of the plane:

$$\partial_{\bar{z}} \frac{1}{z - w} = -\pi \delta^{(2)}(z - w), \quad (28)$$

$$\partial_z \frac{1}{\bar{z} - \bar{w}} = -\pi \delta^{(2)}(z - w). \quad (29)$$

With $\omega \equiv \frac{eB}{m^*c}$, we can rewrite (22) as

$$H = \frac{2\hbar^2}{m^*} \sum_j D_{\bar{z}_j} D_{z_j} + \frac{N}{2} \hbar \omega + \frac{2\hbar^2}{m^*} \pi m \sum_j \sum_{k=1, k \neq j}^N \delta^{(2)}(z_j - z_k) T_j \otimes T_k. \quad (30)$$

Since this Hamiltonian is derived from the assumption that the underlying configuration space is not simply connected, the ground state of H can be obtained by letting $z_j \neq z_k$ for all j and k , and then consider the following first order equation for j -th electron:

$$D_{z_j} \psi_{0j} = \left[\partial_{z_j} + \frac{eB}{4\hbar c} \bar{z}_j - m \sum_{k=1, k \neq j}^N \frac{T_j \otimes T_k}{z_j - z_k} \right] \psi_{0j} = 0. \quad (31)$$

Writing

$$\psi_{0j} = \exp\left(-\frac{1}{4\ell^2} |z_j|^2\right) f_j(z_1, \dots, z_N), \quad (32)$$

equation (31) then becomes

$$\partial_{z_j} f_j(z_1, \dots, z_N) - m \sum_{k=1, k \neq j}^N \frac{T_j \otimes T_k}{z_j - z_k} f_j(z_1, \dots, z_N) = 0. \quad (33)$$

Thus, we see that *chiral* Kniznik-Zamolodchikov equations are relevant in FQHE. For $T_j = 1$, $j = 1, \dots, N$, the holomorphic function satisfying (33) is

$$f_j(z_1, \dots, z_N) = \text{const} \prod_{k=1, k \neq j}^N (z_j - z_k)^m. \quad (34)$$

For $m > 0$, f_j vanishes whenever z_j coincides with any other z_k . In other words, particle j is kept apart from the other electrons. This solution is consistent with the repulsive delta-function potential $\sum_{k=1, k \neq j}^N \delta^{(2)}(z_j - z_k)$, because for any j ,

$$\int dz_j d\bar{z}_j \left(\sum_{k=1, k \neq j}^N \delta^{(2)}(z_j - z_k) \right) |f_j|^2 = 0. \quad (35)$$

Though f_j is not normalizable, ψ_{0j} is, thanks to the factor $\exp(-\frac{1}{4\ell^2}|z_j|^2)$ contributed by the strong magnetic field. Solving $D_{z_j}\psi_{0j} = 0$ for arbitrary j , we find that the solution is exactly the Laughlin wavefunction $|m\rangle$.

2.3 Topological excitations

In [4], Laughlin gave an ansatz of the wavefunction which is a 1-quasi-hole excitation of the ground state $|m\rangle$ (21):

$$\psi_m(u; z_1, \dots, z_N) = \prod_{j=1}^N (z_j - u) |m\rangle, \quad (36)$$

where u is the position of the quasi-hole. The existence of the quasi-hole excitation is demonstrated in the *gedanken* experiment. An infinitesimally thin solenoid is pierced through the ground state $|m\rangle$ at position u . Adiabatically, a flux quantum $\frac{hc}{e}$ is added; $|m\rangle$ evolves in such a way that it remains an eigenstate of the changing Hamiltonian. After the flux tube is completely installed, the resulting Hamiltonian is related to the initial one by a (singular) gauge transformation. To get back to the original Hamiltonian, the flux tube is gauged away, leaving behind an excited state $\psi_m(u; z_1, \dots, z_N)$.

Motivated by this physical picture, we consider the same Hamiltonian (22) for the 1-quasi-hole excitation but with a gauge transformed $A_{z_j}, A_{\bar{z}_j}$:

$$\begin{aligned} A_{z_j} &\rightarrow im\hbar \sum_{k=1, k \neq j}^N \left(\frac{1}{z_j - z_k} + \frac{\frac{1}{m}}{z_j - u} \right), \\ A_{\bar{z}_j} &\rightarrow -im\hbar \sum_{k=1, k \neq j}^N \left(\frac{1}{\bar{z}_j - \bar{z}_k} + \frac{\frac{1}{m}}{\bar{z}_j - \bar{u}} \right). \end{aligned} \quad (37)$$

It can be easily verified that ψ_m satisfy the ground state equations, $j = 1, \dots, N$:

$$\left[\partial_{z_j} + \frac{eB}{4\hbar c} \bar{z}_j - m \sum_{k=1, k \neq j}^N \left(\frac{1}{z_j - z_k} + \frac{\frac{1}{m}}{z_j - u} \right) \right] \psi_m = 0. \quad (38)$$

Recall that $A_{z_j}, A_{\bar{z}_j}$ originate from the *charged* winding number constraint of the paths of particle j in the multiply-connected configuration space. Attaching an additional solenoid on $|m\rangle$ therefore results in a new configuration space. In other words, electron j sees the quasi-hole as a puncture as well, but this time with charge $q_h = \frac{1}{m}$. The excitation is topological in nature. When a quasi-hole develops, the configuration space is topologically changed; an additional puncture has appeared.

The scenario of many quasi-holes is given by the Halperin ansatz [22]:

$$\psi_m(u_1, \dots, u_{N_h}) = \prod_{1 \leq j < k \leq N_h} (u_j - u_k)^{\frac{1}{m}} \exp\left(-\frac{1}{4m\ell^2} \sum_i |u_i|^2\right) \prod_{j,k} (u_j - z_k) |m\rangle. \quad (39)$$

If we write

$$|\frac{1}{m}\rangle = \prod_{1 \leq j < k \leq N_h} (u_j - u_k)^{\frac{1}{m}} \exp\left(-\frac{1}{4m\ell^2} \sum_i |u_i|^2\right), \quad (40)$$

which is of the same form as Laughlin's ground state $|m\rangle$, we find that

$$\psi_m = |\frac{1}{m}\rangle |m\rangle \prod_{j,k} (u_j - z_k). \quad (41)$$

Written in this form, the physical content of a collection of quasi-holes $|\frac{1}{m}\rangle$ is explicit. They are just “electrons” of (representation) charge $q_h = \frac{1}{m}$ in the “puncture” phase! The quasi-holes are also under the influence of the external magnetic field. The exponential factor $\exp(-\frac{1}{4m\ell^2} \sum_i |u_i|^2)$ is required to make the wavefunction normalizable. The Hamiltonian for two species of electrons labelled by $q = 1$ and $q_h = \frac{1}{m}$ is

$$\begin{aligned} H = & \frac{2\hbar^2}{m^*} \sum_j^N D_{\bar{z}_j} D_{z_j} + \frac{N}{2} \hbar \omega + \frac{2\hbar^2}{m^*} \pi m \sum_j \sum_{k=1, k \neq j} \delta^{(2)}(z_j - z_k) \\ & + \frac{2\hbar^2}{m_h^*} \sum_j^{N_h} d_{\bar{u}_j} d_{u_j} + \frac{N_h}{2} \hbar \omega_h + \frac{2\hbar^2}{m_h^*} \pi \frac{1}{m} \sum_j \sum_{k=1, k \neq j} \delta^{(2)}(u_j - u_k) \\ & + 2\hbar^2 \pi \left(\frac{1}{m^*} + \frac{1}{m_h^*} \right) \sum_j^{N_h} \sum_k^N \delta^{(2)}(u_j - z_k). \end{aligned} \quad (42)$$

where

$$\begin{aligned} D_{z_j} &= \partial_{z_j} + \frac{eB}{4\hbar c} \bar{z}_j - m \sum_{k=1, k \neq j}^N \frac{1 \times 1}{z_j - z_k} - m \sum_{k=1}^{N_h} \frac{1 \times \frac{1}{m}}{z_j - u_k} \\ d_{u_j} &= \partial_{u_j} + \frac{eB}{4\hbar c} \bar{u}_j - m \sum_{k=1, k \neq j}^{N_h} \frac{\frac{1}{m} \times \frac{1}{m}}{u_j - u_k} - m \sum_{k=1}^N \frac{\frac{1}{m} \times 1}{u_j - z_k}, \end{aligned} \quad (43)$$

with similar expressions for $D_{\bar{z}_j}$ and $d_{\bar{u}_j}$. We have denoted the “mass” of a quasi-hole as m_h^* , and $\omega_h = \frac{1}{m} \frac{eB}{m_h^* c}$ is the angular frequency of the cyclotron motion of the quasi-holes [17]. It can be readily shown that $\psi_m(u_1, \dots, u_{N_h}; z_1, \dots, z_N)$ is the *exact* ground state solution of H (42).

3 Particles on double-sheeted surface

So far, we only considered non-relativistic particles moving on a plane. It is possible to generalize the representation theory to particles moving on a many-sheeted surface. The motivation for doing this is to suggest an alternative to the notion of pseudo-spin [15] in the discussion of FQHE of bilayered samples. As will be discussed subsequently, we find that it is more natural to follow the geometrical route, especially when the electronic system contains more than two layers.

We shall begin with a short revision of Riemann's original proposal [20]. Suppose we have a many-to-one mapping from a z -plane to w -plane such as $w = z^n$, where $n > 1$ is an integer. In this example, n distinct points in the z -plane is mapped to the same point in the w -plane. In other words, distinct points in the z -plane have the same coordinates in the w -plane. Now, suppose physical observations can only be done in the w -plane. In order to reflect the true origin of the underlying geometry, which is the z -plane, one can assign a tag to the points. It is clear that with respect to the mapping $w = z^n$, the z -plane can be divided into sectors each bounded by two angles $\frac{k-1}{n}2\pi$ and $\frac{k}{n}2\pi$, $k = 1, \dots, n$. There is a one-to-one correspondence between each sector and the w -plane. So one can assign a tag k to each point in the z -plane, according to the sector each belongs. Those from the same sector carries the same tag. We say that points with tag k lie in the k -th sheet. The sheets can be joined together at a "cut" along the positive axis of the w -plane, which gives rise to an upper and a lower "edge" for each sheet. The lower edge of the first sheet is "glued" to the upper edge of the second sheet, and the lower edge of the second sheet to the upper edge of the third, and so on. Finally, the lower edge of the n th sheet is glued to the upper edge of the first sheet. With these formal "cutting" and "gluing" procedures, the w -plane becomes a n -sheeted surface.

We are now ready to consider the path integral of particles on the n -sheeted w -plane. For a start, we take $n = 2$ to keep the equations from becoming bombastic. In complete analogy to the representation theory studied in the last section, we assume that the particles moving in the w -plane are in the puncture phase. Since w -plane is double-sheeted, the coordinates of the particles carry either tag $[1]$, or $[2]$. This is tantamount to saying that we have two kinds of particles taking part in the puncture phase.

Let the number of particles with tag $[1]$ be $N^{[1]}$ and that of particles with tag $[2]$ $N^{[2]}$. With the assignment of tags to the particles, we can provide similar distinguishing label for the *charged* winding number $s^{[ij]}$:

$$s^{[ij]} = \frac{1}{2\pi i} \int_C \frac{dz_a^{[i]}}{z_a^{[i]} - z_b^{[j]}} T_a^{[i]} \otimes T_b^{[j]}. \quad (44)$$

where $i = 1, 2$; $j = 1, 2$ are tag numbers, and a, b names given to the particles. Notice that we have $s^{[ij]} = s^{[ji]}$ if all the particles carry the same representation, *i.e.* $T_a^{[i]} = T_b^{[j]}$ for

all i, j, a and b . Now, with the introduction of new tags $[i]$, the charged winding number becomes

$$\begin{pmatrix} s^{[11]} & s^{[12]} \\ s^{[21]} & s^{[22]} \end{pmatrix}. \quad (45)$$

Correspondingly, the homotopic constraint is $\delta^2(2\pi L - \Theta)$, where L is a matrix with 4 entries [§]:

$$L = (L^{[ij]}) = \begin{pmatrix} l^{[11]} T_a^{[11]} \otimes T_b^{[11]} & l^{[12]} T_a^{[12]} \otimes T_b^{[12]} \\ l^{[21]} T_a^{[21]} \otimes T_b^{[21]} & l^{[22]} T_a^{[22]} \otimes T_b^{[22]} \end{pmatrix}, \quad (46)$$

and Θ is also a matrix $\Theta = (\theta^{[ij]})$ with 4 entries, each entry being

$$\begin{aligned} \theta^{[ij]} &= \text{sign}(C) |\theta_{t_1}^{[ij]} - \theta_{t_0}^{[ij]}| + 2\pi s^{[ij]} \\ &\equiv \vartheta^{[ij]} + 2\pi s^{[ij]}. \end{aligned} \quad (47)$$

The path-ordered Fourier transform of the constraint is,

$$\frac{1}{4\pi^2} \iint dk^{[ij]} \bar{k}^{[ij]} e^{-i(k^{[ij]} \vartheta^{[ij]} + \bar{k}^{[ij]} \vartheta^{[ij]})} \text{P exp } i[2\pi k^{[ij]} (L^{[ij]} - s^{[ij]}) + a.c.], \quad (48)$$

where the Lagrange multipliers $k^{[ij]}$ form a matrix in correspondence to (45):

$$\begin{pmatrix} k^{[11]} & k^{[12]} \\ k^{[21]} & k^{[22]} \end{pmatrix}. \quad (49)$$

In this way, we obtain the partition function of the paths $w_a^{[1]}$ belonging to the homotopy class L :

$$\begin{aligned} &\int \mathcal{D}w_a^{[1]} \mathcal{D}\bar{w}_a^{[1]} \text{P exp } i \int_{t_0}^{t_1} \frac{1}{2} m_a^{[1]} |\dot{w}_a^{[1]}|^2 dt \\ &\quad \times \exp i \int_{t_0}^{t_1} k^{[11]} \left(\frac{i\dot{w}_a^{[1]}}{w_a^{[1]} - w_b^{[1]}} + 2\pi l^{[11]} \right) T_a^{[1]} \otimes T_b^{[1]} \\ &\quad + k^{[12]} \sum_b \left(\frac{i\dot{w}_a^{[1]}}{w_a^{[1]} - w_b^{[2]}} + 2\pi l^{[12]} \right) T_a^{[1]} \otimes T_b^{[2]} \\ &\quad + a.c. dt. \end{aligned} \quad (50)$$

The partition functions of the paths of $w_b^{[1]}$, $w_a^{[2]}$ and $w_b^{[2]}$ belonging to the homotopy class L are similar. These expressions may look complicated but they are based on the same idea discussed in the previous section. The only difference of course is that the paths are tagged and we have to consider them separately although they are on the same plane.

[§]If the charges are nonabelian, each entry itself is a matrix.

Having discussed the puncture phase of four particles $w_a^{[1]}$, $w_b^{[1]}$, $w_a^{[2]}$ and $w_b^{[2]}$, we can go on to consider the multi-particle case. As anticipated, the gauge potential is

$$A_{w_a^{[i]}} = ik^{[ij]} \sum_{b \neq a \text{ if } i=j} \frac{T_a^{[i]} \otimes T_b^{[j]}}{w_a^{[i]} - w_b^{[j]}}, \quad (51)$$

$$\bar{A}_{w_a^{[i]}} = i\bar{k}^{[ij]} \sum_{b \neq a \text{ if } i=j} \frac{\bar{T}_a^{[i]} \otimes \bar{T}_b^{[j]}}{\bar{w}_a^{[i]} - \bar{w}_b^{[j]}}. \quad (52)$$

The novel feature of particles moving on a double-sheeted surface is that the coupling constant of the gauge field is now a matrix (49).

This is the most important consequence of having two different categories of particles on the same plane. For particles with tag $[1]$, they not only see each other as puncture through the coupling constant $k^{[11]}$, but also those with tag $[2]$ through $k^{[12]}$. Similarly, the same can be said for particles with tag $[2]$. If one considers a special case where $k^{[11]} = k^{[12]} = k^{[21]} = k^{[22]}$, one reverts back to the situation of particles moving on a single-sheeted plane, which was the subject we have studied in section 2.

The non-trivial result of the present approach is clearly visible when $k^{[11]} \neq k^{[12]}$ and $k^{[12]} \neq k^{[22]}$. It gives rise to the so-called mutual statistics [10], which is realized between the quasi-excitations of the electron fluid in layer 1 and those in layer 2 of a bilayered sample exhibiting FQHE. This will be further discussed in the next section when we consider the fractional statistics of the quasi-hole excitation of the bilayered FQHE.

The braid group associated with particles moving on a double-sheeted surface is generated by σ_a , $a = 1, \dots, N^{[1]} + N^{[2]} - 1$. Algebraically, the generators satisfy the same defining relations. At the intuitive level, we can imagine weaving two kinds of threads distinguished by their colours; we have $N^{[1]}$ threads of one colour and $N^{[2]}$ threads of another colour. Though there is nothing new about these generators, the representation theory using path integrals however contains a richer flavour. We see that the concept of mutual statistics emerges naturally from the framework. The path integral approach compliments the field theoretic model based on a *generalized* Chern-Simons action [11], as well as the heuristic arguments of attaching *fictitious* flux tubes on the charge carriers [1].

Let us briefly comment on the link with generalized Chern-Simons theory [11] which is defined by the following Lagrangian:

$$\mathcal{L} = \frac{1}{4\pi} \sum_{i,j} \epsilon^{\mu\nu\lambda} \alpha_\mu^{[i]} \lambda^{[ij]} \partial_\nu \alpha_\lambda^{[j]}. \quad (53)$$

For simplicity, we only consider the $U(1)$ case. Different kinds of gauge fields $\alpha^{[i]}$ are involved here. They are coupled to each other via coupling constants $\lambda^{[ij]}$. In the Coulomb

gauge, $a_0^{[i]} = 0$, the induced Gauss law for the generalized system is

$$f_{w_a^{[i]} \bar{w}_a^{[i]}}^{[i]} = -2\pi \sum_{b \neq a} \sum_{i=j=1}^2 (\lambda^{-1})^{[ij]} \delta^2(w_a^{[i]} - w_b^{[j]}), \quad (54)$$

where $i = 1, 2$, and $f_{w_a^{[i]} \bar{w}_a^{[i]}}^{[i]}$ are the components of the field strength. Implicitly, we have assumed that the matrix $\lambda = (\lambda^{[ij]})$ is invertible. If we equate $(\lambda^{-1})^{[ij]} = k^{[ij]}$, we find that the gauge potential (51, 52) arising from the topological effect satisfies the induced Gauss law.

The Hamiltonian suggested by the path integral representation of the braid group is

$$H_a^{[1]} = -\frac{1}{m_a^{[1]}} \left(D_a^{[1]} \bar{D}_a^{[1]} + \bar{D}_a^{[1]} D_a^{[1]} \right) \quad (55)$$

for a free particle named a and of tag $[1]$. In the Schrödinger representation, the differential operator $D_a^{[1]}$ is,

$$\partial_{w_a^{[1]}} - iA_{w_a^{[1]}} \equiv \frac{\partial}{\partial w_a^{[1]}} + k^{[11]} \sum_{b \neq a}^{N^{[1]}} \frac{T_a^{[1]} \otimes T_b^{[1]}}{w_a^{[1]} - w_b^{[1]}} + k^{[12]} \sum_b^{N^{[2]}} \frac{T_a^{[1]} \otimes T_b^{[2]}}{w_a^{[1]} - w_b^{[2]}}. \quad (56)$$

The expression for $\bar{D}_a^{[1]}$ is the anti-chiral analogue of (56). The Hamiltonian for a free particle of tag $[2]$ is of the same form as (55, 56), with $1 \leftrightarrow 2$.

4 FQHE in bilayered systems

The recent discovery of $\nu = \frac{1}{2}$ FQHE state on a bilayered system [12, 13] gives supporting evidence to the theoretical prediction based on the numerical studies of the YMG ansatz $\psi_{m_1, m_2, n}$ (2) [15] with $m_1 = m_2 = 3$ and $n = 1$. The interesting feature of the bilayered system is that electrons in different layers are also strongly correlated. Among other things, the inter-layer correlation seems to be dependent on the distance d between the centres of the quantum wells. In a typical setup where FQHE occurs, the magnetic length ℓ is about 100 Å. The samples used in [13] have two 180-Å wide GaAs quantum wells separated by an undoped AlAs layer 31 Å wide which acts as a potential barrier. The experimental results show that $\nu = \frac{1}{2}$ effect is strongest when $\frac{d}{\ell}$ is 2.4 and the effect weakens when $\frac{d}{\ell}$ increases. The result agrees with YMG's numerical calculation of the overlap between the ground-state wavefunction of a total of 6 electrons and $\psi_{3,3,1}$. The key idea behind the ansatz lies in the prescription of a pseudo quantum number to distinguish electrons in different layers. The wavefunction $\psi_{m_1, m_2, n}$ was first conceived by Halperin [22] to

describe spin-unpolarized single-layered FQHE. By definition, Halperin wavefunction has $m_1 = m_2$. Furthermore, because the spin of an electron is a good quantum number, the singlet condition forces $n = m_1 - 1$ [17]. In the case of spin-polarized double-layered FQHE discussed by YMG, the restriction no longer applies, as the electron-electron interaction depends on the layer in which the electrons reside. In particular, the $\psi_{3,3,1}$ wavefunction is not the eigenstate of the pseudo-spin, which means that it is *not* the ground state in the limit $d \rightarrow 0$. So, the important consequence of YMG ansatz is that the $\nu = \frac{1}{2}$ FQHE state of Laughlin type can only be observed in the double-layered system.

4.1 Ground state equations of the bilayered FQHE

As reviewed in section 2, we have produced a Hamiltonian for which Laughlin wavefunction is the *exact* ground state. Naturally, one wants to do likewise for $\psi_{m_1, m_2, n}$. Having constructed the path integral representation of the braid group of double-sheeted surface, it is possible and in fact rather straightforward to think of a Hamiltonian which yields $\psi_{m_1, m_2, n}$ as ground state.

First, we shall point out some unusual aspect of $\psi_{m_1, m_2, n}$. Strictly speaking, when $d \neq 0$, there is no a priori reason why $\prod (w_a^{[1]} - w_b^{[2]})^n$ should appear. In fact, even when $w_a^{[1]} = w_b^{[2]}$, the two electrons from the respective layers are still a distance d apart. This is not true for electrons moving in the same layer. Though energetically unfavourable, electrons in the same layer can come arbitrarily close to one another as in the event of collision; there is no physical barrier to enforce that they be at least a distance d apart. How are we going to incorporate the asymmetry between inter-layer and intra-layer electron-electron interaction?

In our proposal to understand the FQHE as a manifestation of the puncture phase [17], we have particularly emphasized the role played by the cyclotron motion. The point is that in order for the electrons to see each other as punctures, we need each electron whirl with high frequency to effectively exclude the region enclosed by the motion from being accessible to other electrons. When the background magnetic field is high enough such that this is achieved, literally the cyclotron motion has created puncture. The physical intuition compares favourably with the fact that a threshold in the background field strength B exists, below which plateaux dissolve; the excitation energy vanishes when B drops below certain critical value. Given this picture, one realizes that the electrons in the same layer are forbidden to come close to each other; not closer than 2ℓ when the transition to puncture phase occurs. Viewed in this light, the asymmetry alluded to disappears.

But this is only half the story. Remember that the layers are separated in the direction of the magnetic field. The inter-layer and intra-layer interactions are strictly speaking, mutually orthogonal. Since the wavefunction $\psi_{m_1, m_2, n}$ does not contain information about

the coordinates in the direction of the magnetic field, it is only an approximation of the actual system. Nevertheless, there are reasons to believe that $\psi_{m_1, m_2, n}$ is a good approximation of the FQHE ground state at the large scale. Compared to the size of the sample, both d and ℓ are small. They can be seen as some UV cutoff of an effective field theory which is topological in nature. One of the important insights springing from the use of Chern-Simons action as an effective theory is that the Hall conductivity of the system is identifiable as the inverse of the so-called level k of the topological gauge theory [21], which is defined on a space-time with two spatial dimensions. Thus, the width of the quantum well is ignored. As it turns out, despite the cavalier tone of the approximation, it is alright to do so when we restrict the discussion to robust quantities such as the filling factor, and the statistics and charges of the quasi-excitations.

From the perspective of braid group, we have also captured the topological aspect of the FQHE. As reviewed in section 2, it was shown that Laughlin wavefunction is an exact solution of the ground state equation. Given that the FQHE is inherently associated with some topological order, it is therefore tempting to find out if the inter-layer correlation of the bilayered system is also of similar nature.

To begin with, we project the two layers onto a common 2-dimensional plane which takes care of the remaining asymmetry between the inter-layer and intra-layer correlation. In other words, we assign a tag to indicate which of the two layers the electrons are originally from. Effectively, tagging the particles renders the 2-dimensional plane multi-sheeted. The tag is the only information one has about the direction parallel to the magnetic field. For a bilayered system, we have two kinds of particles on the plane. Suppose the electron gas enters the puncture phase. The quantum mechanics of this system of electrons with effective mass m^* is then given by the following Hamiltonian:

$$H = -\frac{1}{m^*} \left(\sum_a^{N^{[1]}} (D_a^{[1]} \bar{D}_a^{[1]} + \bar{D}_a^{[1]} D_a^{[1]}) + \sum_a^{N^{[2]}} (D_a^{[1]} \bar{D}_a^{[2]} + \bar{D}_a^{[1]} D_a^{[2]}) \right), \quad (57)$$

where in the symmetric gauge, the differential operator $D_a^{[1]}$ is

$$D_a^{[1]} \equiv \frac{\partial}{\partial w_a^{[1]}} + \frac{eB}{4\hbar c} \bar{w}_a^{[1]} - k^{[11]} \sum_{b \neq a}^{N^{[1]}} \frac{1 \times 1}{w_a^{[1]} - w_b^{[1]}} - k^{[12]} \sum_b^{N^{[2]}} \frac{1 \times 1}{w_a^{[1]} - w_b^{[2]}} \quad (58)$$

The other operators $\bar{D}_a^{[1]}$, $D_a^{[2]}$ and $\bar{D}_a^{[2]}$ are similarly defined. We can solve the ground state equations

$$D_a^{[i]} \psi = 0 \quad (59)$$

for every a and i . It is readily verifiable that $\psi_{m_1, m_2, n}$ is a solution of the equations, with

$$k^{[11]} = m_1, \quad (60)$$

$$k^{[12]} = n, \quad (61)$$

$$k^{[22]} = m_2. \quad (62)$$

The filling fraction of $\psi_{m_1, m_2, n}$ is

$$\nu = \frac{m_1 + m_2 - 2n}{\Delta}, \quad (63)$$

where Δ is the determinant of the matrix (49), namely

$$\Delta = \det \begin{pmatrix} m_1 & n \\ n & m_2 \end{pmatrix}. \quad (64)$$

ν is obtained as follows. The inverse matrix of (64) is

$$\begin{pmatrix} \frac{m_2}{\Delta} & \frac{-n}{\Delta} \\ \frac{-n}{\Delta} & \frac{m_1}{\Delta} \end{pmatrix}, \quad (65)$$

and ν is defined as the sum of all the entries of the inverse matrix (65). The prescription to yield the filling fraction ν is a generalization of the single-layered case where $\nu = \frac{1}{m}$, *i.e.* ν is (the sum of the entries of) the inverse (matrix) of m , regarded as a 1×1 matrix m . As discussed earlier, the identification $\nu = m^{-1}$ has been made from the field theoretic point of view [21]. It also agrees with the braid group approach, since in the Knizhnik-Zamolodchikov equations (33), the level of the corresponding current algebra is the inverse of m (see section 2).

Our result (63) agrees with that based on the intuitive arguments [10]. Let us redo Wilczek's calculation of ν for the layered Hall media [10] in the braid group approach. When the representation charge carried by the puncture is $U(1)$, as in the case of polarized electrons in FQHE, there is a kind of “duality” between m and the charge. For example:

$$\partial_z - m \sum_i^N \frac{1 \times 1}{z - w_i} = \partial_z - \sum_i^N \frac{1 \times m}{z - w_i}. \quad (66)$$

In words, particle z of (representation) charge 1 unit sensing punctures w_i of charge 1 unit with the coupling strength m is the same as sensing punctures of charge m units with unit strength. The total flux that particle z sees is mN . Using this “duality”, electrons of layer 1 sensing electrons of layer 2 with strength n is equivalent to sensing “fractionally charged” electrons of charge $\frac{n}{m_1}$ with strength m_1 . Vice versa, electrons of layer 2 see fractionally charged electrons of layer 1 with strength $\frac{n}{m_2}$. Now, the total flux that each electron of layer 1 sees is

$$\Phi^{[1]} \equiv m_1(N^{[1]} - 1 + \frac{n}{m_1}N^{[2]}), \quad (67)$$

while every electron of layer 2 sees a total of

$$\Phi^{[2]} \equiv m_2(N^{[2]} - 1 + \frac{n}{m_2}N^{[1]}) \quad (68)$$

units of flux. The crucial point is that at the large scale limit, the two layers are in equilibrium and therefore $\Phi^{[1]} = \Phi^{[2]}$, which is

$$(N^{[1]} - 1)m_1 + N^{[2]}n = N^{[1]}n + (N^{[2]} - 1)m_2. \quad (69)$$

Put in words, regardless of whichever layer the electron is in, the number of flux each sees in its surrounding is the same. This is not surprising because both layers are radiated with the same magnetic field. Using the usual expression of ν in the study of quantum Hall effect

$$\nu = \frac{\text{total no. of electrons}}{\text{total no. of flux}} \quad (70)$$

$$= \frac{N^{[1]} + N^{[2]}}{N^{[1]}m_1 + N^{[2]}n}, \quad (71)$$

Taking the limit $N^{[1]} \rightarrow \infty$ and $N^{[2]} \rightarrow \infty$, we obtain from (69),

$$\nu \rightarrow \frac{m_1 + m_2 - 2n}{m_1m_2 - n^2}. \quad (72)$$

It is gratifying that the calculation of ν from the inverse matrix (65) as suggested by the effective topological field theory [11] yields the same result from the usual formula (71). These two methods are tied together in the braid group approach.

4.2 Quasi-hole excitations

In complete analogy to the case of single-layered FQHE, one can consider quasi-hole excitation on the double-sheeted surface. The quasi-holes too pick up a tag, corresponding to either of the layers they belong. Suppose the magnetic field is slightly varied such that there is a surplus of magnetic flux. Let the number of quasi-holes in the first layer and the second layer be N_1 and N_2 respectively. These quasi-holes are fractionally charged excitations. We denote their (representation) charges as c_1 and c_2 respectively.

One can determine the values of c_1 and c_2 as follows. As has been discussed in the literature, quasi-holes behave much like electrons, except they are fractionally charged. Therefore, they also engage themselves in the puncture phase. In addition to (67) that each electron of tag [1] sees, it also senses the flux carried by the quasi-holes:

$$m_1c_1N_1 + nc_2N_2 = N_1. \quad (73)$$

Similarly, each electron of tag [2] senses an additional

$$m_2 c_2 N_2 + n c_1 N_1 = N_2 \quad (74)$$

units of flux. Since both layers are immersed in the same background magnetic field, small variation in the field strength should result in the same number of extra fluxes (which are buffered by the quasi-holes). In other words, $N_1 = N_2$.

Therefore, we get the following two equations:

$$m_1 c_1 + n c_2 = 1, \quad (75)$$

$$m_2 c_2 + n c_1 = 1. \quad (76)$$

Written in the matrix form, we have

$$\begin{pmatrix} m_1 & n \\ n & m_2 \end{pmatrix} \begin{pmatrix} c_1 \\ c_2 \end{pmatrix} = \begin{pmatrix} 1 \\ 1 \end{pmatrix}. \quad (77)$$

Once again, the matrix of coupling constants appears. Solving these two equations, one readily finds that

$$c_1 = \frac{m_2 - n}{\Delta}, \quad (78)$$

$$c_2 = \frac{m_1 - n}{\Delta}. \quad (79)$$

This result was first obtained by Wilczek [10] who applied the adiabatic theorem discussed in [23]. It is curious to notice that c_1 is equal to the sum of the entries in the first row of the inverse matrix of the coupling matrix, and c_2 the sum of the entries in the second row. In fact, the matrix equation (77) expresses these equalities which are also obtainable from the generalized Chern-Simons approach [11].

With the physical picture offered by the path integral representation of the braid group, we can proceed to write down the many-quasi-hole wavefunction of the bilayered system:

$$\begin{aligned} \psi &\equiv \prod_{a < b} (u_a^{[1]} - u_b^{[1]})^{m_1 c_1^2} \prod_{a, b} (u_a^{[1]} - u_b^{[2]})^{n c_1 c_2} \prod_{a < b} (u_a^{[2]} - u_b^{[2]})^{m_2 c_2^2} \\ &\times \prod (w_a^{[1]} - u_b^{[1]})^{m_1 c_1} \prod (w_a^{[2]} - u_b^{[2]})^{m_2 c_2} \prod (w_a^{[1]} - u_b^{[2]})^{n c_2} \prod (w_a^{[2]} - u_b^{[1]})^{n c_1} \\ &\times \exp\left(-\frac{1}{4\ell^2 c_1} \sum_a^{N_1} |u_a^{[1]}|^2 - \frac{1}{4\ell^2 c_2} \sum_a^{N_2} |u_a^{[2]}|^2\right) \psi_{m_1, m_2, n} \end{aligned} \quad (80)$$

This wavefunction is an exact solution of the bilayered version of the ground state equations:

$$\left(\mathcal{D}_a^{[i]} + \frac{e}{c[i]} \frac{B}{4\hbar c} \overline{u}_a^{[i]} \right) \psi = 0, \quad (81)$$

where

$$\begin{aligned}
\mathcal{D}_a^{[1]} &\equiv \partial_{u_a^{[1]}} - m_1 \sum_{b \neq a}^{N_1} \frac{c_1 \times c_1}{u_a^{[1]} - u_b^{[1]}} - n \sum_b^{N_2} \frac{c_1 \times c_2}{u_a^{[1]} - u_b^{[2]}} - m_1 \sum_b^{N^{[1]}} \frac{c_1 \times 1}{u_a^{[1]} - w_b^{[1]}} - n \sum_b^{N^{[2]}} \frac{c_1 \times 1}{u_a^{[1]} - w_b^{[2]}} \\
&= \partial_{u_a^{[1]}} - m_1 c_1 \sum_{b \neq a}^{N_1} \frac{1 \times c_1}{u_a^{[1]} - u_b^{[1]}} - m_1 c_1 \sum_b^{N_2} \frac{1 \times \frac{n}{m_1} c_2}{u_a^{[1]} - u_b^{[2]}} \\
&\quad - m_1 c_1 \sum_b^{N^{[1]}} \frac{1 \times 1}{u_a^{[1]} - w_b^{[1]}} - m_1 c_1 \sum_b^{N^{[2]}} \frac{1 \times \frac{n}{m_1}}{u_a^{[1]} - w_b^{[2]}} ,
\end{aligned} \tag{82}$$

and

$$\begin{aligned}
\mathcal{D}_a^{[2]} &\equiv \partial_{u_a^{[2]}} - m_2 \sum_{b \neq a}^{N_2} \frac{c_2 \times c_2}{u_a^{[2]} - u_b^{[2]}} - n \sum_b^{N_1} \frac{c_2 \times c_1}{u_a^{[2]} - u_b^{[1]}} - m_2 \sum_b^{N^{[2]}} \frac{c_2 \times 1}{u_a^{[2]} - w_b^{[2]}} - n \sum_b^{N^{[1]}} \frac{c_2 \times 1}{u_a^{[2]} - w_b^{[1]}} \\
&= \partial_{u_a^{[2]}} - m_2 c_2 \sum_{b \neq a}^{N_2} \frac{1 \times c_2}{u_a^{[2]} - u_b^{[2]}} - m_2 c_2 \sum_b^{N_1} \frac{1 \times \frac{n}{m_2} c_1}{u_a^{[2]} - u_b^{[1]}} \\
&\quad - m_2 c_2 \sum_b^{N^{[2]}} \frac{1 \times 1}{u_a^{[2]} - w_b^{[2]}} - m_2 c_2 \sum_b^{N^{[1]}} \frac{1 \times \frac{n}{m_2}}{u_a^{[2]} - w_b^{[1]}} .
\end{aligned} \tag{83}$$

The statistical parameters of the quasi-holes are easily readable from (80) and they are

$$\frac{\theta^{[11]}}{\pi} = m_1 c_1^2 , \tag{84}$$

$$\frac{\theta^{[12]}}{\pi} = n c_1 c_2 , \tag{85}$$

$$\frac{\theta^{[22]}}{\pi} = m_2 c_2^2 . \tag{86}$$

We have checked that these values coincide with those calculated with the generalized Chern-Simons approach [11]. $\frac{\theta^{[12]}}{\pi}$ is the *mutual statistics* of the quasi-holes residing in different layers.

5 Discussions

5.1 Inter-layer correlation

The braid group formalism leading to the ground state equations (81) does not specify the relation between m_1, m_2 and n . Much like m_1 and m_2 are restricted to odd integers due to the Pauli principle, we shall explore the possible values of n from physical considerations.

First of all, n must be an integer because the charge carriers are electrons and the wavefunction of the total system must be single-valued with respect to monodromy. It is also evident that if $\delta = \frac{d}{\ell}$ is large, which corresponds to two isolated single layers, the inter-layer correlation should weaken, if not vanishes. On the other extreme, when d is zero, which is the usual single-layered setup, the total number of (polarized) electrons in the layer is $N^{[1]} + N^{[2]}$ and $m_1 = m_2 = n$. In this instance, the 2×2 matrix (49) collapses to a number m_1 (otherwise it becomes singular). The point is that n strictly depends on δ , which is an indicator of the onset of inter-layer correlation.

Next, we want to propose that n should be an odd number as well. The physical picture emerging from electrons moving on a double-sheeted surface is that electrons with tag [1] and those with [2] should be *effectively* indistinguishable as well. This is because the magneto-transport measurement is performed on the total system and thus cannot possibly distinguish which of the two layers the electrons are from. In a certain sense, the bilayered system is analogous to a d. c. circuit of two resistors in parallel. Before and after the electrons flow through the resistors, there is no way to tell which of the two resistors each is going to pass or has passed. Assigning a tag to the coordinates does not make the electrons distinguishable, just like giving a name a does not make the electrons of the same layer distinguishable. Therefore, invoking Pauli principle, n is restricted to be an odd number.

Though it is far more difficult to justify, we feel that n should be smaller than m_1 and m_2 . The braid group approach reveals that these numbers are the strengths with which an electron sees its counterparts as punctures. Given this interpretation, it is therefore expected that electrons sense those of the same layer with greater strength than those from different layer. Summarizing what have been said so far, $n = n(\delta)$, and it monotonously decreases from m_1 (or m_2 , whichever is smaller) to 0.

5.2 Mutual statistics

It is now clear that mutual statistics arises in bilayered system because of $k^{[12]} \neq 0$. Since $k^{[12]} = n$ is a function of δ as discussed earlier, it is the consequence of inter-layer correlation. In the braid group approach, electrons from both layers participate in the puncture phase on the double-sheeted surface. Within an appropriate range of δ , n takes on non-trivial value and mutual statistics is realized.

5.3 Coupling matrix and multi-layered FQHE

The method we use to study the bilayered FQHE can be easily extended to multi-layered systems. It is straightforward to generalize the construction discussed in section 3 by replacing double-sheeted surface with multi-sheeted plane. The path integral repre-

sentation of the braid group now involves a $M \times M$ matrix of coupling constants:

$$\begin{pmatrix} k^{[11]} & k^{[12]} & \dots & k^{[1M]} \\ k^{[21]} & k^{[22]} & \dots & k^{[2M]} \\ \vdots & \vdots & \ddots & \vdots \\ k^{[M1]} & k^{[M2]} & \dots & k^{[MM]} \end{pmatrix} \quad (87)$$

The coupling matrix (87) compactly encodes the topological information of an ensemble of free electrons moving in a multi-sheeted surface. The filling factor of the multi-layered Hall fluid is the sum of all the entries of the inverse matrix of (87). The dimension of the coupling matrix corresponds to the number of layers of the electronic system. When the Hall media is single-layered, the coupling matrix is 1×1 and (87) reduces to just one number, the inverse of which gives the filling factor of Laughlin type. Therefore, the coupling matrix is a generalization of the usual description of single-layered FQHE. For example, consider the following coupling matrix:

$$\begin{pmatrix} m_1 & n & 0 \\ n & m_2 & n \\ 0 & n & m_3 \end{pmatrix}. \quad (88)$$

It describes a Hall media of three layers. Calculating the sum of all the entries of the inverse matrix of (88), we find that the filling factor is

$$\nu = \frac{m_1 m_2 + m_1 m_3 + m_2 m_3 - 2m_1 n - 2m_3 n}{m_1 m_2 m_3 - m_1 n^2 - m_3 n^2}. \quad (89)$$

One can check that (89) coincides with the usual calculation. The equilibrium condition is

$$m_1[(N^{[1]} - 1) + N^{[2]} \frac{n}{m_1}] = m_2[N^{[1]} \frac{n}{m_2} + (N^{[2]} - 1) + N^{[3]} \frac{n}{m_2}] = m_3[N^{[2]} \frac{n}{m_3} + (N^{[3]} - 1)]. \quad (90)$$

In the limit $N^{[i]} \rightarrow \infty$ for all i , the formula (71) yields the same value as (89). If $m_i = 3$ and $n = 1$, $\nu = \frac{5}{7}$. This should be the 3-layered analogue of the $\nu = \frac{1}{2}$ effect observed by [13].

5.4 3-dimensional FQHE

Suppose there are many layers, such that the dimension M of the coupling matrix is large. It is then possible to contemplate a multi-layered FQHE characterized by the

following coupling matrix:

$$\begin{pmatrix} m_1 & n & 0 & \cdots & \cdots & 0 \\ n & m_2 & n & \cdots & \cdots & \vdots \\ 0 & n & m_3 & \ddots & & \vdots \\ \vdots & \vdots & \ddots & \ddots & \ddots & \vdots \\ \vdots & \vdots & & \ddots & m_{M-1} & n \\ 0 & 0 & \cdots & \cdots & n & m_M \end{pmatrix} \quad (91)$$

The symmetric tridiagonal coupling matrix (91) is an interesting case because it corresponds to the nearest-neighbour inter-layer correlation which is more likely to be realized experimentally. Now when the number of layers M is large, the electronic system is literally 3-dimensional! Since each layer correlates only with its nearest layers, the model can be regarded as locally 2-dimensional. By juxtaposing narrow quantum wells alternately with barriers of appropriate width, one may create 3-dimensional FQHE in the laboratory.

6 Concluding remarks

The representation theory of the braid group over the multi-sheeted surface has clearly given us a useful basis to consider the physics of multi-layered Hall media. The most interesting feature of the multi-layered FQHE, as compared to single-layered FQHE, is the notion of fractional mutual statistics. We have proposed a Hamiltonian (57) for which the YMG ansatz (2) is the *exact* solution of the ground state equations. As in the single-layered case, the topological order of the multi-layered system lies in the “puncture phase” wherein each particle sees the rest as punctures on the multi-sheeted surface.

The braid group approach presents us a tool, namely the coupling matrix (87) to capture the filling factors, fractional charges and statistics of the quasi-excitations of the multi-layered FQHE. It is worthwhile to highlight that a $\nu = \frac{5}{7}$ effect is predicted for a sample with three layers of electron fluid. Finally, if one has the technology to grow many layers of heterojunctions, it is even possible to realize a 3-dimensional FQHE described by the coupling matrix (91).

Acknowledgement

I would like to thank C. H. Lai for encouragement and discussions, and C. L. Ho for a useful conversation on “duality”.

Note added

After this paper was submitted for publication, I learned that Ezawa and Iwazaki had also independently considered the concept of mutual statistics (which they called relative statistics) in [24].
